# DOES THE NEW “GREEN ARCHITECTURE” OF THE CAP PROVIDE A CHANCE FOR THE CONSERVATION OF LAPWINGS (*VANELLUS VANELLUS*)? FINDINGS FROM DISCRETE CHOICE EXPERIMENTS WITH GERMAN ARABLE FARMERS

## Abstract

Growing evidence suggests that biodiversity in the agricultural landscape is declining sharply. Farmland birds are particularly affected, e.g. the lapwing (*Vanellus vanellus*) population has been decreasing strongly in Germany and Europe. Up to now the European Union has tried to tackle the problem of biodiversity loss mainly with voluntary (second pillar) agri-environmental schemes financed by the European Agricultural Fund for Rural Development (EAFRD). However, only a small fraction of the agricultural land is enrolled in such programs. We analyse different schemes promoting lapwings in order to identify drivers and inhibitors of acceptance. The analysis is based on a discrete choice experiment with 270 arable farmers in Germany. Results show that those scheme attributes associated with EAFRD compliance, the type of sanctioning and a minimum participation period of five years, markedly reduce the farmers' acceptance.

The results have several policy implications. First, it shows clearly that the maximum support rates for agri-environmental and climate measures according to Art. 28 of EU 1305/2013 laid down in Annex 2 are set too low to achieve an effective implementation of the measure. Second, Eco-Schemes which are an element of the European Commission's legislative proposal for the Common Agricultural Policy (CAP) could be a valid option to address some of the identified caveats. Eco-Schemes that shall be part of the future direct payments will presumably produce higher participation rates since they offer greater flexibility due to the minimum period of only one year and the late timing of the farmers' decision until mid-May of the running year. In addition, they could provide additional basic income support and not just compensate for the income loss associated with the protection measure.

## Key Words

Biodiversity protection, lapwing, agri-environmental schemes, discrete choice experiments

## 1. Introduction

Growing evidence suggests that biodiversity in the agricultural landscape is declining sharply. For farmland birds this is well documented as in the European Union they have declined by 30% since 1990 (LEOPOLDINA, 2018; EBCC, 2017). Farmland bird abundance and diversity can be interpreted as a proxy for biodiversity on farming landscapes in general (SCHOLEFIELD ET AL., 2011). Up to now the European Union has tried to tackle this problem mainly with voluntary (second pillar) agri-environmental schemes financed by the European Agricultural Fund for Rural Development (EAFRD). However, farmers often do not take up these programs in a sufficient extent to achieve an impact on the targeted populations. Only a small fraction of the agricultural land is enrolled in agri-environmental schemes tackling biodiversity issues like fallow and field strips (PABST et al., 2018; RÖDER et al., 2018).

We analyse a potential agri-environmental scheme to protect the lapwing in order to identify drivers and inhibitors of acceptance. The lapwing (*Vanellus vanellus*) is a farmland bird that stands exemplary for several endangered species of agriculturally used landscapes. The population has been decreasing sharply in Germany. Compared to 1990, the population in 2015 declined by three-fourth (DDA, 2019). This is mainly because of a low breeding success, which is due to several factors especially a grassland management too intensive to allow the survival of the chicks (too dense swards mown too frequently) (ROODBERGEN et al., 2012). In Germany, nowadays over half of the population breeds on arable land, mainly on spring

crops. However, the frequent cultivation measures during the nesting period lead to a high risk of nest destruction (Personal communication with HERMANN HÖTKER<sup>1</sup>). One of the most effective measures to increase breeding success on arable fields is a lapwing plot (SHELDON et al., 2007). A lapwing plot is an area of 0.5 to 2-hectare, ploughed before the breeding period to create an area of bare soil or open sward in early spring. The lapwing plot remains unmanaged during the breeding season from mid-March until the end of June. It provides food, space for breeding and creates cover for the chicks to hide from raptors.

With respect to acceptance of this measure we address the following research questions: Which characteristics of the support scheme influence the farmers' acceptance of the plots and to which extent? How high is the expected remuneration and how is it influenced by different characteristics of the scheme? How do different groups of farmers differ in terms of their potential participation in the scheme?

The analysis is based on a discrete choice experiment with 270 arable farmers in Germany. Several authors have undertaken discrete choice experiments to determine acceptance towards potential or existing agri-environmental schemes. The works refer to various contexts and different schemes, but nevertheless some common patterns emerge from the results. Early studies from WYNN et al. (2001) and VANSLEMBROUCK et al. (2002) emphasise that - besides levels of payments - characteristics of the required measure practices are of major importance for acceptance as they have to fit farm production contexts (WYNN et al., 2001). In many studies we observe that flexibility in scheme structure increases the farmers' utility. Flexibility means that there are as many options as possible for scheme properties, for example the size of the area to be included (ESPINOSA-GODED et al., 2010). Flexibility may also contain the possibility to cancel the contract (BROCH and VEDEL, 2012) or to have a short-term contract in comparison to a long-term contract (RUTO and GARROD, 2009). Further, some authors have included regulatory aspects in their choice experiments such as monitoring (BROCH and VEDEL, 2012) and a fine in case of infringement (ALLÓ et al., 2015) which both decrease farmers' utility.

The studies also identified farmers' characteristics indicating a greater probability to participate, such as farmers that are younger and better educated than the average (ALLÓ et al., 2015; RUTO and GARROD, 2009). Farmers with experience in agri-environmental schemes (VANSLEMBROUCK et al., 2002; BREUSTEDT et al., 2013), with a positive attitude to the environment (RUTO and GARROD, 2009; BREUSTEDT et al., 2013) or towards the effectiveness of agri-environmental programs (VANSLEMBROUCK et al., 2002) derive a greater utility from such programs. Farms' characteristics are also important. Farmers with extensively managed holdings and those with distant, poorly tailored and low-yielding areas are more likely to participate, because their opportunity costs are comparatively low. Managers of intensive farms on the other hand expect higher payments (BREUSTEDT et al., 2013). The role of farm size is more ambivalent. RUTO and GARROD (2009) and ALLÓ et al. (2015) determine that owners of large farms have a higher participation probability or value the payments more positively than the average. VANSLEMBROUCK et al. (2002) show that the connection may depend on the type of protection measure. In one measure of their study, the highest participation probability is linked to the largest farms; in another measure, however, to the smallest.

The results from the literature review serve as one reference point to derive the research design for our discrete choice experiment. However, above all, we developed the design and hypothesis from the specific context of the lapwing plot that we tested with farmers in field works. After an introduction into the methodology of discrete choice modelling in the next chapter (2.1), we will describe the research design in chapter 2.2, the survey and sampling in

---

<sup>1</sup> Mr. HÖTKER is head of Michael-Otto-Institute of the German Nature and Biodiversity Conservation Union.

chapter 2.3 and model specification in chapter 2.4. Thereafter we will present (chapter 3) and discuss (chapter 4) the results and finish with concluding remarks.

## 2. Methodology

### 2.1 Discrete choice modelling

The methodological approach in designing and evaluating the survey is discrete choice experiments (DCE) (HENSHER et al., 2015; TRAIN, 2009). This means that farmers were presented successively with different combinations of protection measure attributes from which they could choose. From the responses, the independent influence of the different attributes on measure acceptance can be estimated. Systematic variation of measure attributes is - to our knowledge - only possible with discrete choice experiments. For example, with contingent valuation one can only vary remuneration expectations, but not other attributes (HANLEY et al., 2001).

In microeconomic theory, choosing for a certain alternative is associated with the utility that the decision maker, in our case a farmer, expects from the alternative. The theoretic basis for DCE is random utility theory which divides utility  $U$  of an alternative  $j$  and a person  $n$  (farmer) into a deterministic component  $V$  and a random component  $\varepsilon$ .

$$(1) U_{nj} = V_{nj}(X_j) + \varepsilon_{nj} = \beta' x_{nj} + \varepsilon_{nj}$$

The deterministic component  $V$  consists of a vector of attributes  $x$  that describe the alternative, for example the remuneration that the farmer receives. The aim is to estimate the parameters  $\beta$  of the different attributes  $x$  influencing utility. We cannot directly measure utility of a certain alternative. But we know from random utility theory, that the farmer maximizes his or her utility by choosing alternative  $i$  (out of  $j$ ) from which he or she expects the greatest utility. The probability that the farmer chooses alternative  $i$  is as high as the probability that the utility derived from  $i$  is higher than the utility from any other of the given alternatives  $j$  (Adamowicz et al., 1998).

$$(2) P_{ni} = P[(U_{ni} > U_{nj}) \forall j \neq i] = P[(V_{ni} - V_{nj}) > (\varepsilon_{nj} - \varepsilon_{ni})]$$

Under the condition that the error terms  $\varepsilon_{nj}$  are independent und identically distributed, equation (2) can be converted into equation (3) (Train, 2009).

$$(3) P_{ni} = \frac{e^{\beta' x_{ni}}}{\sum_j e^{\beta' x_{nj}}}$$

Equation (3) is the conditional logit function whose parameters  $\beta$  are estimated with a maximum likelihood estimator. Conditional logit (CL) models come along with the assumption that parameters are unique for all respondents. Since this is behaviourally inappropriate, we apply a random parameter logit (RPL) model for estimation processes. It takes into account heterogeneity of parameter values  $\beta$  over decision makers  $n$  with density  $f(\beta|\theta)$  where  $\theta$  refers e. g. to the means and the covariates of parameters  $\beta$ .

$$(4) U_{nj} = \beta'_n x_{nj} + \varepsilon_{nj} \quad \beta_n \sim f(\theta)$$

Further the RPL model relaxes other problematic CL assumption, such as independence of choices and independence of irrelevant alternatives (Hensher et al., 2015). In the RPL estimation procedure, distribution moments of  $\beta_n$ , such as means and covariates, are estimated. This works by simulation of different distributions of coefficients  $\beta_n$  with density  $f(\beta|\theta)$ . The functional form (e. g. normal distribution) of the distributions needs to be predetermined. By maximum likelihood estimation, simulated distributions are computationally repeated and optimized until the calculated choice probabilities are as close as possible to the observed choices. Choice probabilities are calculated with an open-form integral over all possible parameters  $\beta_n$

$$(5) P_{ni} = \int_{\beta_n} L_{ni}(\beta_n) f(\beta_n | \theta) d\beta_n,$$

where  $L_{ni}(\beta_n)$  is the standard logit probability (NARJES and LIPPERT, 2014).

Once the parameters are estimated, it is useful to interpret them by means of willingness to accept (WTA). WTA expresses the marginal need for compensation (remuneration) associated with level (or one unit) change in a variable. In other words, how much more or less remuneration, does the farmer expect if one protection measure variable changes the level (or unit), in our case, for example, the change of the contract period from one to five years. WTA is calculated by establishing the negative ratio of the variable parameter  $\beta_k$  and the remuneration parameter  $\beta_c$ . If non-linear variables are effects coded, as it is the case here, the ratio needs to be multiplied by two.

$$(6) WTA = -2 \frac{\beta_k}{\beta_c}.$$

## 2.2 Hypotheses and experimental design

Based on literature research, interviews and group discussions with farmers, who tested the lapwing plot between 2015 and 2017, we worked out options how to design the protection measure. We were guided by the two partly conflicting aims of achieving the highest possible breeding success and complying with certain regulatory and administrative standards so that the measure can be implemented in the framework of an agri-environmental program. The group discussions took place in September 2017 in Braunschweig (region with predominate sugar beet and silage maize cultivation) and Münsterland (predominate silage maize cultivation). The aim was to discuss the acceptance of the measure options, to refine their design and to derive working hypotheses. Table 1 lists the attributes and levels that we finally used in the discrete choice experiment (DCE) (columns 1 and 2). Columns 3, 4 and 5 show one example of a choice card, i.e. different combinations of attribute levels that we presented the farmers and from which they could choose.

**Table 1: Attributes, attribute levels and one example of a choice card**

Attribute levels	Attribute	Example of a choice card		
		Option A	Option B	
<ul style="list-style-type: none"> <li>Bare soil, no seeding: soil cultivation until 15.03.</li> <li>Open sward: seeding with a grass clover mixture until 15.03.</li> </ul>	Seeding with a grass clover mixture	Seeding	No seeding	No participation
<ul style="list-style-type: none"> <li>At the field margin</li> <li>In the field</li> </ul>	Position of the lapwing plot	At the field margin	In the field	
<ul style="list-style-type: none"> <li>Marking of lapwings' nests</li> <li>No marking</li> </ul>	Obligatory marking of nests on cultivated part of the field	No	No	
One year / five years	Contract duration	Five years	One year	
<ul style="list-style-type: none"> <li>Low: 7 % of remuneration</li> <li>High: 7 % of remuneration + 3 % of the farm's direct payments</li> </ul>	Level of sanctions in case of an infringement	High	Low	
700 / 1000 / 1300 / 1600 €/ha	Remuneration	1300 €/ha	700 €/ha	

Source: Author

The first attribute describes that the farmer either seeds the lapwing plot with a grass clover mixture (until 15.03.) or he alternatively creates bare soil conditions by for example harrowing (until 15.03). Seeding establishes an open sward that creates cover for the chicks to

hide from raptors. Further, the grass clover mixture shall limit the establishment of weeds. However, farmers may fear that the grass clover mixture actually leads to weeds on the lapwing plot that could spread to other parts of the field. Moreover, seeding means additional work for the farmer.

The second attribute describes the lapwing plot's position in the arable field. In the discussions most farmers prefer the plot to be located at the field margin, because it is easier to manage with machinery. However, the position within the field is advantageous for the breeding success because fewer disturbances can be expected (e.g. from dogs on tracks). SHELDON et al. (2007) identified distance of the lapwing plot to field boundaries as one of the best explaining variables for chick survival rates.

The third attribute implies the option that lapwing nests are marked so that farmers drive around them when applying cultivation measures. This refers to the cultivated part of the arable field and not the lapwing plot itself (where cultivation measures are forbidden). Lapwings not only breed on "their" plots, but also on the rest of the field, so that marking these nests is an additional measure to increase breeding success. From the farmers' point of view, driving around nest markings is an additional effort. But they don't have to make the markings themselves. This is done by local ornithologists.

Attributes 4 and 5 (period of the measure and level of sanctions) are decisive to whether the measure can be co-financed by the European Union's (EU) European Agricultural Fund for Rural Development (EAFRD). Both a minimum participation period of five years (EU, 2013: Article 28(5)) and the type of sanctioning (COM, 2014: Articles 15ff.), described as high in Table 1, are linked with EAFRD compliance.

Attribute 6 implies the potential remuneration levels that we derived from gross margin calculations for different crops so that they compensate yield losses. Some of the levels have been tested during field trials with farmers. The lowest and the highest levels represent the lower and the upper bound of what we considered ex-ante to be a realistic range.

Against the background of the arguments given above, we derived the following hypotheses with regard to attribute level preferences:

1. *The higher the yearly remuneration payments per ha, the greater the probability that farmers participate in the protection measure.*
2. *Farmers prefer the lapwing plot to be at the field margin rather than in the middle of the field, so that this position increases participation probability.*
3. *Marking nests on the cultivated part of the field reduces the benefit of the measure from the farmer's point of view reducing participation probability.*
4. *The preference for either bare soil or open sward on the lapwing plot varies among farmers. This should be reflected in parameter standard deviations markedly different from zero.*
5. *Farmers prefer the measure period to be one year instead of five years so that the one-year period increases participation probability.*
6. *Farmers prefer the measure if the sanction level is low instead of high so that the low sanction level increases participation probability.*

We further hypothesized the probability of participation in dependence of farmers' and the farms' characteristics:

7. *Farmers with a high or very high affinity towards protection of rare animal species are more likely to participate.*
8. *Farmers with experience in area-based measures comparable to the lapwing plot are more likely to participate.*
9. *Farmers with experience in voluntary agri-environmental measures (e. g. contractual nature conservation) are more likely to participate.*

10. *Farmers with a high share of unproductive or unfavourable arable fields are more likely to participate.*

In the survey, farmers were first generally introduced to the lapwing plot. Then we presented a list of compulsory funding requirements that had been consolidated from the field trials, e.g. range of plot size and minimum distances to trees, hedges and roads. Subsequently, the farmers were presented and explained the different attributes and attribute levels. In the next step we presented the farmer with choice cards for which we gave an example in Table 1. Since there are numerous ways to combine attribute levels in the choice cards, we used N-gene software to determine the combinations. In the pretest (with 19 farmers) we used an orthogonal design for the determination. From the parameter estimations of the pretest we determined priors to create an efficient design of choice cards for the final survey. An efficient design enables parameter estimation with as low as possible standard errors (CHOICEMETRICS, 2014). We optimized the efficient design for analysis with random parameter logit models and yielded a D-error of 0.08. In the final design, we used 20 choice cards with 2 blocks, i. e. each respondent answered 10 choice cards. The sequence of choice cards was shuffled for each respondent.

In the second part of the survey we asked the respondents about their attitudes towards the protection of rare species and their experience in protection measures comparable to the lapwing plot. Further we asked respondents to provide information on their farm (e. g. number of livestock) and socio-economic characteristics (e. g. age).

### **2.3 Survey and sampling**

We conducted the survey from January to March 2018 via the online panel "agri EXPERTS" (<https://www.agri-experts.de>) and the website "agrarheute.com". A total of 284 farmers cultivating spring crops fully completed the survey. However, we only evaluated 270 questionnaires because 14 respondents spent less than 8 minutes completing the survey. We consider this period to be too short to ensure a meaningful answer to the questions.<sup>2</sup> Of the 270 respondents, 211 (78 %) came from the panel and 59 (22 %) from the website. The panel includes 1209 arable farmers, so that for the panel a response rate of 17 % could be achieved.

In the following we compare our sample with the total population in terms of important characteristics (Table 2) such as size of farm and arable land which constitutes the target area of the lapwing plot. The total population represents all farmers in Germany who cultivate spring crops. However, the agricultural structure in Germany differs considerably in different areas so that farms cannot be directly compared. That is why Table 2 not only shows the whole sample (column 3), but we have divided our sample and the total population into regional subgroups (THÜNEN ATLAS, 2010; STATISTISCHE ÄMTER DES BUNDES UND DER LÄNDER, 2016). Column 4 shows that in our sample 126 respondents come from the German federal states of Schleswig-Holstein, Lower Saxony and North Rhine-Westphalia. These states have a comparable agricultural structure and the respondents are thus grouped in the region "North". We compare this group with the total population of farmers originating from these federal states and cultivating spring crops (column 5) (RDC, 2016). 93 respondents are from Baden-Württemberg and Bavaria who we grouped in the region "South". The remaining 51 respondents come from different federal states. Here, however, the number of cases is so small that we do not consider a comparison with the total population useful.

In the sample, farms from the North are overrepresented with a share of 47% in comparison to a share of 33% in the total population, whereas farms from the South are underrepresented. In both regions, farms in our sample are larger than in the total population, in the North the

---

<sup>2</sup> The distribution of the participation duration among respondents shows that the number of respondents rises sharply from 8 minutes, so that we assume a meaningful survey duration from this point.

respective percentiles are roughly twice as large as in the population. In the South, differences are a bit less pronounced. Accordingly, the size of arable land per farm is double as high or even more in both regions. Also, the share of arable land per farm is larger in the sample than in the total population. With regard to livestock, 50% (median) of respondents in both regions do not have any livestock at all which is not the case in the total population. With regard to the 75<sup>th</sup> percentile we observe livestock units per ha considerably lower than in the total population. Only for 5% of the farms in our sample (95<sup>th</sup> percentile) we observe livestock density that is greater than in the total population. Also, the share of farms with cattle is much lower in our sample with about 30% versus about 50% in the total population.

**Table 2: Descriptive statistics for the sample in comparison to the total population**

Variable		Survey data overall	Survey data North	FSS North	Survey data South	FSS South

FSS= Farm structure survey. FSS data of the age of the farm's operating manager does not relate to the total population, but is based on an extrapolation of a sample.

Source: RDC (2016) and own calculations.

The share of farms cultivating different spring crops in our sample is mostly comparable with the total population. Differences are usually up to about 10%. Only the share of farms

growing sugar beet is considerably higher in our sample than in the total population. The age of the farms' operating managers is overall comparable.

## 2.4 Model specifications

We used NLOGIT 6 econometric software to analyze the discrete choice experiment data. As each of the 270 respondents answered 10 choice sets, we had 2 700 choice observations. The attributes described in chapter 2.2 entered the estimated model as non-linear variables (Table 3). We attributed value one to the options given in plain text. Non-linear variables are effects-coded so that the base levels are not perfectly confounded with the opt-out alternative which would be the case if the variables were dummy-coded (HENSHER ET AL., 2015). Effects-coding is especially important because we estimate the constant (BECH and GYRD-HANSEN, 2005). Only for the attribute "remuneration" a quantitative variable was assigned, which means that the coefficient expresses the utility increase of one unit (Euro). The constant enters the model as non-linear variable with value one for participation in the protection measure (either option A or B). The constant expresses the utility of participation independent of the attributes. All attributes and the constant<sup>3</sup> were randomized in order to reveal preference heterogeneity with 100 Halton draw sequences and the assumption of normal distributions (cf. chapter 2.1). Only the parameter "remuneration" is fixed so that we are able to determine economically meaningful WTA estimates. Covariates entered the model as (non-random) interaction terms with the constant.

## 3. Results

Overall, the model has a good fit with a pseudo  $R^2$  of 0.34 (HENSHER et al., 2015) and a chi-square of 2 032 with 34 degrees of freedom<sup>4</sup> (Table 3). Coefficients of non-random parameters and coefficient means of random-parameters have the expected signs. They support hypotheses 1-3 and 5-6 given in chapter 2.2. We did not hypothesize on a general preference for either bare soil or open sward conditions on the lapwing plot. Results show that on average there is a preference for open sward since bare soils decrease utility in comparison to open sward. In this context, we rather hypothesized that preferences vary among farmers. The corresponding hypothesis 4 is supported by a random parameter standard deviation markedly different from zero. All other random parameter standard deviations are also markedly different from zero expressing heterogeneity in preferences. The reasons for this require further analysis. The coefficient for the constant is negative. This result is not surprising since it expresses the utility of participation independent of the attributes, thus independent of remuneration. Also for the constant we observe a standard deviation markedly different from zero.

We further tested the influence of farmers' and farms' characteristics on the participation probability (hypotheses 7-10) by creating interaction terms of the characteristics and the constant. The coefficients' positive signs indicate that farmers with an affinity for the protection of rare species and farmers with experience with area-based measures (e. g. flowering strips) are more likely to participate in the lapwing plot than those farmers not having the corresponding affinity or experience. However, farmers with experience in voluntary agri-environmental measures (e. g. contractual nature conservation) are not necessarily more likely to participate. The effect is unclear, reflected by the high standard error. Thus, hypothesis 9 is not supported.

---

<sup>3</sup> Randomizing the constant is possible in case of a panel model that we use here (Greene, 2012: p. 536).

<sup>4</sup> We refrain the discussion of significance tests because we do not claim that our sample is representative of all farmers growing spring crops in Germany. The comparison between the sample and the total population has shown that there are some structural differences, e.g. in the farm sizes. However, significance tests refer only to random errors (Wasserstein und Lazar, 2016; Amrhein et al., 2019).

**Table 3: Random Parameter Logit results**

Variable	Coefficient	Standard error	p-value Wald test	95% confidence interval	
<b>Random parameter means</b>

Further, farmers who manage at least 5 % of unproductive or unfavourable arable land (e.g. small plots, difficult to reach, often wet) have a higher participation probability than those farmers managing less than 5 % of such land. In addition to the hypotheses made in advance, we have tested the influence of weed pressure. Farmers who, according to their self-assessment, have mean weed pressure on their land are more likely to participate than those with high weed pressure. Farmers with low weed pressure, however, are less likely to participate than those with high weed pressure.

**Figure 1: Mean probability of participation in dependence of remuneration, length and sanction (favourable conditions for other attributes and covariates)**

Source: Author

Among the attributes, those relating to EAFRD compliance in particular have a high effect. We will illustrate this in the following. Once the coefficients are estimated, equation 3 can be used to calculate the choice probability as a function of the attributes and covariates. Figure 1 shows the mean probability of participation in dependence of remuneration, length and sanction. The probabilities shown refer to favourable conditions with respect to the other attributes and co-variables, i. e. the lapwing isle is at the field margin, the farm has more than 5 % unproductive plots etc. The solid line shows the participation probability with no EAFRD compliance. More than 80 % probability can be reached with a remuneration of 700 €. Introducing high sanctions leads to a strong shift of the curve to the right and downwards. 80 % probability can only be reached with a remuneration of about 1 050€. Additional introduction of five years length further shifts the curve and leads to payment expectation of 1 500€/ha for a choice probability of 80 %.

**Table 4: Willingness to accept (WTA) for attributes and covariates**

Variable	Mean WTA (€/ha)	Standard error (€/ha)	95% confidence interval (€/ha)	
<b>Attributes</b>				
Plot at the field margin vs in the field	-132	34	-198	-66
No marking of nests vs marking of nest	-246	38	-320	-172

In Figure 1 we have seen by how much the remuneration expectation changes if one variable changes its level and we intend to reach the same participation probability. This can also be expressed by mean willingness to accept (WTA) (cf. chapter 2.1), given for all attributes and covariates in Table 4. For example, if no nest markings are made, the expected remuneration declines on average by 246 €/ha. Farmers with an affinity for the protection of rare species on average expect a lower remuneration for the protection measure of about 300 €/ha, independent of specific attributes. For the covariate “experience with voluntary measures” the estimate is subject to a high degree of uncertainty indicated by the relatively high standard error.

#### 4. Discussion and Conclusion

Results show that especially those attributes associated with EAFRD compliance strongly reduce farmers’ acceptance. A minimum participation period of five years and the type of sanctioning linked with EAFRD compliance particularly lower the probability of participation or alternatively raise the compensation requirement. Farmers expect about 424 €/ha and 574 €/ha, respectively, more to achieve the same level of acceptance. Preference for short-term contracts is in line with RUTO and GARROD’s (2009) results and with the often documented general preference for flexibility in agri-environmental schemes (ESPINOSA-GODED et al., 2010; BROCH and VEDEL, 2012). Further our results on sanctions are in line with the general disutility of fines and monitoring observed in BROCH and VEDEL (2012) and ALLÓ et al. (2015). The fear of EAFRD sanctions - even based on unintentional and minor violations - is documented in EAFRD evaluation literature (PABST et al., 2018), but is quantified in our analysis (WTA).

Farmers’ preferences do not necessarily have to contradict ecological requirements as also from an ecological point of view, a shorter participation period of one year makes sense. Lapwings shift their breeding territory every year within a certain radius, depending primarily on the overall supply of bare soil in spring. Other attribute preferences constitute an economic-ecological trade-off. For example, marking of nests increases the breeding success, but WTA for this attribute is 246 €/ha. Interestingly, farmers who participated in the field trials were satisfied with a remuneration of 50 € for the marking and frequently did not expect any money at all. This discrepancy could indicate a selection bias among farmers participating in the field trials. On the other hand, this could also mean that payment expectations may be significantly reduced with appropriate advice and experience.

In general we conclude that barriers of acceptance may be removed by advice, so that biodiversity protection schemes such as the one at hand should be combined with local environmental managers. These managers, having the appropriate, in our case, ornithological knowledge, should help farmers to select suitable areas of land, implement the measure and communicate with the managing authorities. In addition, HÖTKER and JEROMIN (in press) show that in German areas designated for the protection of meadow birds a positive development of the Lapwing population is much more likely if at least one full-time equivalent per 10 000 ha is employed for the area management. Assistance lowers the threshold to participate in the measure, increases the effectiveness of the measure, and reduces the risk of sanctions. Such coordinators could be financed by other programs like the European Regional Development Fund.

The manager’s tasks could also include the acquisition of farmers, whereby it would be advisable to focus on certain groups of farmers. Our results show that farmers with an affinity for the protection of rare species or with experience of other area-based protection measures are more likely to participate. Moreover, some farm characteristics raise the farmers’ participation rates: a high number of unproductive areas and areas of medium weed pressure, compared to high weed pressure.

We cannot attest that our sample is representative of all German farmers growing spring crops. A comparison between our sample and the farming population in certain German federal states was only possible for some criteria for which population data are available. Based on these data, we assume that we somewhat overestimate willingness to participate. In comparison to the total population, farmers in our sample have more arable land and need less land for manure disposal (fewer animals). Thus they probably have higher degrees of freedom to provide ecological services such as the lapwing plot than the farmers of the entire population.

Overall, our results identified weak spots of biodiversity protection schemes, especially regarding those attributes associated with EAFRD compliance. The high WTA sums related to this subject show that the usual remuneration calculation of agri-environmental measures (compensation of income loss) compensates the farmers' utility loss only partially. In fact, the results have shown that without EAFRD compliance (and otherwise favourable conditions) a participation probability of approximately 80% can be achieved with a remuneration of about 700€/ha. This sum corresponds roughly with the compensation of the calculated income loss associated with the measure. However, when introducing attributes associated with EAFRD compliance, WTA sums strongly increase and can be interpreted as a risk premium.

In this context we think that the new "Green Architecture" in the proposals for the CAP past 2020 (COM, 2018a) offer three levies to achieve an increased implementation of environmental friendly farming practices and thereby improve the conservation of lapwings. First, the maximum support rates for agri-environmental schemes defined in Annex II of EU-regulation 1305/2013 are dropped. As shown above these rates are too low for the lapwing plot, especially because the lapwing breeding range is often in areas with intensive agriculture. Second, the member states must define the control and sanctioning system. We regard this as a chance to create a system that is more comprehensible and transparent to farmers (COM, 2018b: Articles 57ff.) in comparison to the current sanctioning system which constitutes one of the greatest barriers of acceptance. Third, the new instrument of Eco-Scheme defined in Art. 28 of COM (2018a) could be a promising tool, because it may be implemented under the first pillar, a support system that farmers are familiar with so that a lower entry barrier can be expected. Furthermore, farmers have only an annual obligation and can modify their decision (extent and location) till mid-May, which suits their preference for flexibility and short-term contracts.

**Acknowledgements:** The authors would like to thank Professor Christian Lippert for his valuable advice on the whole research project. We further like to thank him and Manuel Narjes for their advice on specifying the econometric model.

The project "Lapwing: Conservation measures for a ground-nesting birds", in the context of which this paper was written, is supported by the German Federal Agency for Nature Conservation with funds from the Federal Ministry for the Environment, Nature Conservation and Nuclear Safety as part of the Federal Programme for Biological Diversity.
